Analysis of Cardiac Myocyte Maturation Using CASAAV, a Platform for Rapid Dissection of Cardiac Myocyte Gene Function In Vivo

Yuxuan Guo,* Nathan J. VanDusen,* Lina Zhang, Weiliang Gu, Isha Sethi, Silvia Guatimosim, Qing Ma, Blake D. Jardin, Yulan Ai, Donghui Zhang, Biyi Chen, Ang Guo, Guo-Cheng Yuan, Long-Sheng Song, William T. Pu

Rationale: Loss-of-function studies in cardiac myocytes (CMs) are currently limited by the need for appropriate conditional knockout alleles. The factors that regulate CM maturation are poorly understood. Previous studies on CM maturation have been confounded by heart dysfunction caused by whole organ gene inactivation.

Objective: To develop a new technical platform to rapidly characterize cell-autonomous gene function in postnatal murine CMs and apply it to identify genes that regulate transverse tubules (T-tubules), a hallmark of mature CMs.

Methods and Results: We developed CRISPR/Cas9-AAV9-based somatic mutagenesis, a platform in which AAV9 delivers tandem guide RNAs targeting a gene of interest and cardiac tropinin-T promoter–driven Cre to RosaCasGFP neonatal mice. When directed against junctophilin-2 (Jph2), a gene previously implicated in T-tubule maturation, we achieved efficient, rapid, and CM-specific JPH2 depletion. High-dose AAV9 ablated JPH2 in 64% CMs and caused lethal heart failure, whereas low-dose AAV9 ablated JPH2 in 22% CMs and preserved normal heart function. In the context of preserved heart function, CMs lacking JPH2 developed T-tubules that were nearly morphologically normal, indicating that JPH2 does not have a major, cell-autonomous role in T-tubule maturation. However, in hearts with severe dysfunction, both adeno-associated virus–transduced and nontransduced CMs exhibited T-tubule disruption, which was more severe in the transduced subset. These data indicate that cardiac dysfunction disrupts T-tubule structure and that JPH2 protects T-tubules in this context. We then used CRISPR/Cas9-AAV9-based somatic mutagenesis to screen 8 additional genes for required, cell-autonomous roles in T-tubule formation. We identified RYR2 (Ryanodine Receptor-2) as a novel, cell-autonomously required T-tubule maturation factor.

Conclusions: CRISPR/Cas9-AAV9-based somatic mutagenesis is a powerful tool to study cell-autonomous gene functions. Genetic mosaics are invaluable to accurately define cell-autonomous gene function. JPH2 has a minor role in normal T-tubule maturation but is required to stabilize T-tubules in the failing heart. RYR2 is a novel T-tubule maturation factor. (Circ Res. 2017;120:1874-1888. DOI: 10.1161/CIRCRESAHA.116.310283.)

Key Words: alleles ■ gene silencing ■ heart failure ■ maturation ■ mutagenesis ■ transverse tubule

During mammalian heart development, cardiac myocyte (CM) phenotype changes dramatically between fetal, neonatal, and adult stages.1 Fetal CMs are small, proliferative, and primarily produce energy through glycolysis. In contrast, adult CMs are much larger, terminally differentiated, and primarily produce energy through oxidative phosphorylation. The transition from fetal to adult phenotypes, referred to as CM maturation, occurs most rapidly in the perinatal period in the mouse between the end of gestation and about postnatal day 20 (P20). The mechanisms that govern CM maturation are poorly understood. Presently, maturation of stem cells or nonmyocytes directed to differentiate into CMs is a major hurdle impeding the use of these technologies for disease modeling or therapeutic cardiac regeneration.1 Understanding the factors that regulate endogenous CM maturation would facilitate efforts to overcome this hurdle.

Novelty and Significance

What Is Known?

- Genetic knockout or knockdown is a critical research strategy, but the commonly used approach requires developing and obtaining a different genetically modified mouse line for each gene, which is a slow process.
- Genetic knockout in the cardiac myocyte (CM) compartment often causes cardiac dysfunction, which initiates a panoply of secondary effects that can obscure the direct, cell-autonomous effects of gene inactivation.
- Junctophilin-2 is implicated in development of transverse tubules (T-tubules), a hallmark of CM maturation because knockdown of junctophilin-2 using shRNAs causes heart failure and T-tubule disruption.

What New Information Does This Article Contribute?

- We developed a CM selective, Cas9/AAV9-mediated gene inactivation platform, named CRISPR/Cas9/AAV9-based somatic mutagenesis (CASAAV), that allows efficient inactivation of a gene without developing or acquiring a new mouse line for the gene of interest.
- On administration of different titer libraries of adeno-associated virus constructs, both organ-wide and cell-autonomous effects of gene depletion can be studied, allowing dissection of direct cell-autonomous effects from the secondary effects because of cardiac dysfunction.

Applying CASAAV approach to study T-tubule maturation, we found that junctophilin-2 plays a minor cell-autonomous role in T-tubule maturation, and we uncovered a novel, cell-autonomous role for RYR2 (Ryanodine Receptor-2) in T-tubule maturation.

CM-selective genetic loss of function is a powerful strategy for dissecting gene function in the heart. However, implementing this strategy using the traditional approaches is time-consuming, and results are vulnerable to misinterpretation because of secondary effects caused by organ-wide gene inactivation. Here, we show that a Cas9-based and adeno-associated virus–based platform (CASAAV) permits efficient and rapid gene inactivation, in either a small or large fraction of CMs. We deploy this new method to study T-tubule formation, a hallmark of mature CMs. Using the CASAAV platform, we show that junctophilin-2, a gene previously found to be essential for T-tubule maturation, has a limited role in this process. A CASAAV candidate-based screen uncovered an unanticipated role for RYR2 in T-tubule formation. The CASAAV platform and the mosaic gene inactivation strategy provide avenues to more rapidly and precisely perform in vivo genetic loss-of-function studies in CMs.

Among the most characteristic and latest developing hallmarks of adult CMs are transverse tubules (T-tubules), which start to form at ≈P10 in mouse and become fully mature at ≈P20.2 T-tubules are tubular invaginations of the plasma membrane that penetrate deep within CMs and align with the Z-lines of sarcomeres. The junctional sarcoplasmic reticulum comes in close proximity to T-tubules at specialized membrane microdomains known as dyads, which mediate Ca\(^{2+}\)-induced Ca\(^{2+}\) release, and thereby couples CM electric activity to contraction. The cardiac action potential rapidly spreads along T-tubules, where depolarization activates the L-type Ca\(^{2+}\) channel. The resulting small influx of Ca\(^{2+}\) activates RYR2 (Ryanodine Receptor-2), the major cardiac intracellular Ca\(^{2+}\) release channel located on the junctional sarcoplasmic reticulum (SR). Activated RYR2 releases a large amount of Ca\(^{2+}\), which induces sarcomere contraction. Thus, T-tubules facilitate coordinated Ca\(^{2+}\) release within large adult CMs which could not be achieved through sequential, diffusion-mediated spread of the Ca\(^{2+}\) transient.3,4

Although the physiological functions of T-tubules have been well characterized, the molecular machinery that induces the maturation and maintenance of T-tubules is largely unknown. Junctophilin-2 (JPH2),5,6 a structural protein that is specifically expressed in CMs, uses its N-terminal plasma membrane–binding motifs and C-terminal SR transmembrane domain to tether T-tubule and SR membrane together to form dyads.7 CM-specific knockdown of Jph2 in mouse caused dramatic remodeling and loss of T-tubules during postnatal development.2,8 This result was interpreted as evidence that JPH2 is a critical regulator of T-tubule maturation.2,8 However, JPH2 depletion in this mouse model also causes severe cardiomyopathy and heart failure.2,8 T-tubule disruption is present in hearts with cardiomyopathy and heart failure.9,10 Thus, cardiomyopathy and heart failure confound the interpretation of the Jph2 knockdown phenotype with regard to its role in T-tubule maturation.

The confounding effect of secondary changes caused by cardiac stress response in conventional genetic analyses is a common problem for studies of CM maturation and indeed for cardiac biology in general. Genetic knockouts that induce cardiac dysfunction and failure precipitate a host of indirect secondary effects, and dissecting direct effects of genetic manipulations from secondary effects can be problematic. In this study, we established a platform for quickly producing genetic mosaic knockouts which allow investigation of cell-autonomous effects of gene knockout within the context of normally functioning myocardium. We deployed this platform to precisely characterize CM maturation factors without the interference of heart failure. We found that JPH2 is not required for overall T-tubule formation; rather, it helps to stabilize T-tubules in the face of cardiac dysfunction. We then use this platform and a candidate-based approach to identify novel T-tubule maturation factors. This platform will be useful for dissecting cell-autonomous genetic pathways that regulate postnatal CM maturation and function.
Methods

Materials and Methods are available in the Online Data Supplement.

Adeno-Associated Virus
AAV-U6gRNA-cTNT-Cre plasmid (Online Figure I) was constructed by transferring a CTNT-Cre cassette from AAV-TNT-Cre plasmid11 to PX552 plasmid.12 A second U6gRNA was further added to generate AAV-U6gRNA-U6gRNA-cTNT-Cre (Addgene No. 87682). A total of 20 bp gRNA sequences (Online Table I) were cloned into these plasmids through a single ligation step.

Adeno-associated virus (AAV) was produced and purified using a standard protocol with modifications.13 AAV titer was quantified by quantitative polymerase chain reaction using primers indicated in Online Table II.

Mice
All animal procedures were approved by the Boston Children’s Hospital Institutional Animal Care and Use Committee. AAVs were injected into P1 Rosa26Cas9-GFP mice10 by subcutaneous injection. CMs were dissociated by retrograde collagenase perfusion as described previously.15

Validation and Examination of Jph2 Depletion in CMs
The mRNA level of Jph2 was examined by quantitative reverse transcription polymerase chain reaction (qRT-PCR) using primers shown in Online Table II. The deletion of Jph2 between 2 gRNAs was detected by RT-PCR. Construction of DNA libraries for amplicon sequencing was performed by modifying a published protocol16 using primers shown in Online Table II. Paired-end, 250 bp reads were generated on an Illumina MiSeq and analyzed using CRISPResso software.17 Validation of gene knockout was performed through immunofluorescence. Antibodies and dyes used are listed in Online Table III.

Flow Cytometry
Quantitative analysis by flow cytometry was performed using a Propel Laboratories Avalon cytometer with a 100 μm nozzle and standard GFP/RFP (green/red fluorescence protein) filter sets. Data were further analyzed using BioRad ProSort software.

Quantitative mutagenesis analysis was performed using a BD AriaII SORP cell sorter with a 100 μm nozzle at Dana-Farber flow cytometry core facility.

Analyses of Heart Phenotypes
Gross heart morphology was imaged under a stereomicroscope (Zeiss SteREO Discovery V8) with an AxioCam MRc camera. Heart histology, organ weights, and expression of cardiac stress markers were assayed as described previously.13 Echocardiography was performed on awake animals using a VisualSonics Vevo 2100 with Vevostrainer software. Echocardiography was performed blinded to AAV types and doses.

T-Tubule Imaging and Analysis
In situ T-tubule imaging and AutoTT analysis of T-tubule patterns were performed as described previously.20

Intracellular Ca2+ Recording
Intracellular Ca2+ was measured in isolated CMs that were loaded with Rhod-2 AM (acetoxyethyl). Cells were electrically stimulated at 1 Hz to produce steady-state conditions. All image data were acquired in the line scanning mode along the long axis of the cell using an Olympus FV1000 inverted laser scanning confocal microscope with a 60X/1.3 silicone oil objective.

Statistics
Unless otherwise noted, values are displayed as mean±SD. Statistical comparisons were performed using Student t test. Kaplan–Meier survival analysis was performed using JMP software (SAS).

Results

CRISPR/Cas9/AAV9-Based Somatic Mutagenesis Efficiently Depletes JPH2 in CMs During CM Maturation
Previously our laboratory showed that the heart could tolerate the deletion of essential genes in a small fraction of CMs while still maintaining normal heart function.11 This mosaic analysis allowed us to study CM maturation in individual cells without the interference of secondary effects caused by heart failure. To establish a versatile technical platform that allows mosaic somatic mutagenesis of any gene specifically in CMs, we combined AAV-mediated mosaic transduction11 with CRISPR/Cas9-based in vivo mutagenesis.14,21–24 We constructed AAV vectors that contain 1 or 2 U6 promoter–driven gRNA expression cassettes and a cardiac troponin-T promoter that drives CM-specific expression of Cre recombinase (Figure 1A; Online Figure I). Using these vectors, we generated AAV9,25 a cardiotropic AAV serotype, and subcutaneously injected the replication-deficient virus into Rosa26Cas9-GFP mice that harbor a Cre-inducible Cas9-P2A-GFP allele.14
cTNT-Cre activated the expression of Cas9 and GFP specifically in AAV-transduced CMs, and the U6 promoter drove expression of gRNA(s) in these cells (Figure 1A). Thus, GFP expression allowed us to study CM maturation in individual cells without the interference of secondary effects caused by heart failure, as occurs during CM dissociation and flow cytometry. The net effect is that a
minority of GFP− cells may have undergone Cas9 genome editing, a technical factor that needs to be considered when interpreting data (Discussion). Overall, this pilot experiment demonstrates that the CASAAV system mediates highly efficient gene silencing in CMs in vivo.

Next, we designed 2 gRNAs that target the coding sequence of Jph2 within exon 1, which encodes the first 4 plasma membrane–binding motifs of JPH2 protein (Figure 1C). These gRNAs had at least 3 mismatches to any nontargeted sequences in the mouse reference genome (Online Figure 1).
III A). We generated AA V s that expressed each gRNA individually (Jph2- gRNA1 or Jph2- gRNA2), or both simultaneously (Jph2- gRNA1+2), and injected 1.1×1010 vg/g (viral genomes per gram body weight) AA V into P1 RosaCas9-GFP+ pups. We isolated CMs from P21 hearts and performed immunofluorescence to detect JPH2 protein (Figure 1D). We found that Jph2-gRNA1, Jph2-gRNA2, and Jph2-gRNA1+2 depleted JPH2 immunofluorescence in ≈55%, ≈70%, and ≈80% of GFP+ CMs, respectively (Figure 1E). We also analyzed JPH2 depletion in transduced CMs by using fluorescence-activated cell sorting to purify GFP+ CMs, followed by Western blot (Figure 1F and 1G). Jph2-gRNA1+2 efficiently depleted JPH2 in transduced CMs. The level of BIN1, another protein implicated in T-tubule maturation, was not affected (Figure 1G). The major effect of Jph2-gRNA1+2 was protein depletion rather than truncation (Online Figure IV), although we cannot exclude production of truncated protein in a low fraction of transduced cells. Overall, our data show that Jph2-CASAAV efficiently depleted JPH2 in CMs and that 2 gRNAs were more efficient at achieving protein depletion than each single gRNA.

To determine the mechanisms that mediate this efficient JPH2 depletion, we injected 5.5×1010 vg/g AA V at P1, which is sufficient to transduce ≈75% CMs in the heart (Figure 2). At P7, we extracted RNA from heart apexes and detected significantly decreased Jph2 mRNA after AA V-Jph2gRNA treatment by quantitative RT-PCR (Figure 3A and 3B). Analysis of Jph2 transcript structure by RT-PCR demonstrated that dual-gRNA CASAAV induced deletion of the intervening coding sequence between 2 gRNA targets in a subset of transcripts, which was not observed with either gRNA alone (Figure 3A and 3C). To more precisely define the effect of CASAAV on Jph2 transcripts, we amplified each gRNA-targeted site from cDNA and performed next-generation sequencing (Amplicon-Seq)29 (Figures 2D through 2F and 3A; Online Figure III B and III C). Analysis of these sequences using CRISPResso17 showed that gRNA1 alone generated mutations in 72% of transcripts, and 71% of these mutated reads shift the translational reading frame (Figure 3D). gRNA2 alone generated mutations in 61% of transcripts, and 86% of these mutated reads shift the translational reading frame (Figure 3D). These mutations localized to the expected gRNA cleavage sites (Figure 3E). When both gRNAs were present, frameshift mutations were detected in >80% mutated reads, and these mutations occurred between the 2 gRNA-targeted sites (Figure 3D through 3F). Thus, JPH2 protein depletion induced by CASAAV is because of a combination of frame-shifting mutations and mRNA decrease, potentially resulting from nonsense-mediated decay.29 The use of 2 gRNAs increased the efficiency of both of these effects. Deletion of Jph2 coding sequences that encode critical plasma membrane–binding domains between the 2 gRNA-targeted sites also provides potential mechanisms to perturb the stability and function of JPH2 protein (Figures 1C, 3C, and 3F).

AAV-Mediated Mosaic Infection Avoids Cardiomyopathies Caused by JPH2 Depletion

To determine the effect of AA V dosage on whole organ and individual CM phenotypes, we treated mice with serial dilutions of AA V-gRNA(Jph2)1+2-TNT-Cre, referred to subsequently as AA V-gRNA(Jph2), at P1. We defined the mice receiving 1.1×1010, 6.1×1010, 1.8×1010, and 5.5×1010 vg/g AA V doses as Jph2_Low, Jph2_Mid, Jph2_High, and Jph2_Full groups, respectively. We measured the frequency of transduced CMs at P7 by detecting Cre-dependent GFP expression from the Rosa26Cas9-GFP allele. AA V dose was positively correlated to the myocardial area occupied by GFP+ CMs (Figure 2A). We quantified the frequency of GFP+ CMs in dissociated CM preparations. Jph2_Low, Jph2_Mid, Jph2_High, and Jph2_Full groups expressed GFP in 22%, 47%, 64%, and 75% of CMs, respectively (Figure 2B).

Next, we investigated whether AA V dosage influences the efficiency of JPH2 depletion in individual transduced CMs. We performed immunofluorescence staining of JPH2 in CMs that were treated with different AA V doses at P1 and isolated at P7. The control AA V-TNT-Cre virus (lacking gRNA) was administered at the full dose (5.5×1010 vg/g). Immunostaining of JPH2 was used to measure each cell’s JPH2 expression level, and immunostaining of caveolin-3 (CAV3), a plasma membrane marker, defined the boundary of each single cell (Figure 2C and 2D). We found a ≈70% decrease of JPH2 intensity in Jph2-CASAAV–treated CMs when compared with negative controls, which further confirmed the efficient depletion of JPH2 protein. By immunostaining, there was no detectable difference in intensity between GFP+ CMs that were treated with different doses of AAVs (Figure 2D). To examine the impact of AA V dosage on the efficiency of protein depletion, we performed fluorescence-activated cell sorting of GFP+ cells in each group and analyzed JPH2 expression by Western blotting (Figure 2E). This demonstrated efficient JPH2 depletion in all groups, although the protein remained detectable in the Jph2_Low and Jph2_Mid groups but was undetectable in the Jph2_High and Jph2_Full groups. Thus, AA V dose primarily determines the frequency of transduced CMs. The dose has a small effect on protein depletion efficiency among transduced cells, but even at the lowest dose tested, the protein was efficiently depleted. These findings are important for interpreting the mosaic gene knockout data presented below.

Mice that received the full dose of AA V-gRNA(Jph2) died between P10 and P13 (Figure 4A), which is consistent with the survival curve of Myh6-Cre;Jph2-shRNA mice described previously.4 Mice treated with the other doses of AA V-gRNA(Jph2) survived beyond P20 (Figure 4A), when T-tubules become fully mature.2 Because our goal was to examine the impact of JPH2 on T-tubule maturation, we focused the following studies on Jph2_Low, Jph2_Mid, and Jph2_High groups and studied mice at P21 to P24. Analyses of gross heart morphology showed that Jph2_High and Jph2_Mid groups had cardiac hypertrophy and dilatation, which were not evident in the Jph2_Low group (Figure 4B). This differentiation was quantified by measurement of the heart weight/body weight ratio, which was not elevated in the Jph2_Low group but was increased in Jph2_Mid and Jph2_High groups in a dose-dependent manner (Figure 4C). Echocardiography showed severely depressed heart systolic function in the Jph2_High group (Figure 4D). By contrast, the Jph2_Mid group had moderately depressed heart function, and the
Jph2_Low group did not exhibit detectable heart dysfunction (Figure 4D). AAV-gRNA(Jph2) dosage also correlated with the extent of left ventricular dilatation (Figure 4E and 4F). Expression of cardiac stress markers Myh7, Nppa, and Nppb were consistent with these overall effects of virus dose on heart structure and functions (Figure 4G). Together, these data indicate that high and mid doses of AAV-gRNA(Jph2) caused dose-related cardiac hypertrophy and dysfunction, whereas the low dose did not impact heart function at the organ level.

We next examined the effect of the extent of Jph2 inactivation on the responses of individual CMs. Although induction of heart dysfunction correlated with increased CM size, there was no difference in CM size between GFP⁺ and GFP⁻ CMs at any viral dose (Figure 4H). Thus, JPH2 depletion does not directly affect CM size. Rather, JPH2 affects CM size indirectly through effects on overall organ function.

Collectively, these data show that a low dose of AAV-gRNA(Jph2) can be used to achieve mosaic depletion of JPH2 without affecting overall organ function. Mid and high doses increase the fraction of CMs with gene inactivation and correspondingly cause organ dysfunction and global stress responses.

**JPH2 Plays a Minor Role in T-Tubule Maturation**

Because mosaic Jph2 inactivation by low-dose AAV-gRNA(Jph2) avoided secondary effects of organ dysfunction, we were able to precisely examine the role of JPH2 in T-tubule organization without the confounding effects of cardiac dysfunction. To observe T-tubule organization in live CMs in intact heart ventricles, we labeled T-tubules with the plasma membrane dye FM 4 to 64 through retrograde heart perfusion and performed in situ confocal imaging. We found that T-tubules were dramatically disrupted in GFP⁺ CMs in Jph2_High mice. However, this phenotype was mild in GFP⁺ CMs in Jph2_Mid mice. No overt disruption in T-tubules was observed in GFP⁺ CMs in Jph2_Low mice. This data shows that a low dose of AAV-gRNA(Jph2) can be used to achieve mosaic depletion of JPH2 without affecting overall organ function. Mid and high doses increase the fraction of CMs with gene inactivation and correspondingly cause organ dysfunction and global stress responses.

**Figure 2. Effect of adeno-associated virus (AAV) dosage on the frequency of cardiac myocyte transduction and the extent of Junctophilin-2 (JPH2) depletion.**

longitudinal T-tubule elements, total T-tubule elements (which equal to transverse T-tubule elements + longitudinal T-tubule elements), and T-tubule regularity. Compared with GFP- internal control CMs, GFP+ CMs in Jph2_Low group showed no significant change in T-tubule regularity or longitudinal T-tubule elements and subtly but significantly reduced
transverse T-tubule elements and total T-tubule elements (Figure 5C through 5F). The Jph2_Mid group also showed no significant change in longitudinal T-tubule elements, but a significant impairment in the other 3 parameters was greater than in the Jph2_Low group. All of these parameters were most dramatically impaired in the Jph2_High group. T-tubules in GFP− CMs from Jph2_High mice exhibited T-tubule defects, dramatically impaired in the Jph2_High group. T-tubules in the Jph2_Low group. All of these parameters were most significant impairment in the other 3 parameters was greater than significant change in longitudinal T-tubule elements, but a significant difference in HW/BW (mg/g) and a significant difference in HW/BW (mg/g) between Jph2_Low and control was observed (Figure 6A). By contrast, Jph2_Mid and Jph2_High mice exhibited disrupted CA V3 patterns in these CMs (Figure 6A). Consistent with in situ T-tubule imaging results, JPH2− CMs that were derived from Jph2_Low mice exhibited normal global T-tubule morphology when compared with JPH2− control CMs (Figure 6A). In contrast, Jph2_Mid and Jph2_High mice exhibited disrupted CA V3 patterns in these CMs (Figure 6A). AutoTT quantification of CA V3 immunostaining also showed significantly decreased total T-tubule elements and regularity in JPH2− CMs isolated from Jph2_Mid and Jph2_High mice, but no statistically significant difference between Jph2.Low and control was observed (Figure 6B and (Online Figure V). Together these data demonstrate that JPH2 has a minor cell-autonomous function in T-tubule organization that is exacerbated by heart failure.

To further confirm that these varied phenotypes were not caused by JPH2 depletion efficiency, we performed dual-color immunofluorescence to detect both JPH2 and CA V3 in CMs dissociated from AAV-TNT-Cre (control)–treated and AAV-gRNA(Jph2)–treated mice. This permitted us to identify true JPH2-deficient CMs and examine CA V3 pattern in these CMs (Figure 6A). Consistent with in situ T-tubule imaging results, JPH2− CMs that were derived from Jph2_Low mice exhibited normal global T-tubule morphology when compared with JPH2− control CMs (Figure 6A). In contrast, Jph2_Mid and Jph2_High mice exhibited disrupted CA V3 patterns in these CMs (Figure 6A). AutoTT quantification of CA V3 immunostaining also showed significantly decreased total T-tubule elements and regularity in JPH2− CMs isolated from Jph2_Mid and Jph2_High mice, but no statistically significant difference between Jph2_Low and control was observed (Figure 6B and (Online Figure V).

Figure 4. Dose-dependent induction of myocardial dysfunction by AAV-gRNA(Jph2). CMs were isolated from 3 hearts in each group. Student t test: *P<0.05; **P<0.01; ***P<0.001. Nonsignificant P values are shown in parentheses. Numbers in bars indicate sample size. Plots show mean±SD. Jph2 <0.001. Nonsignificant values are shown in parentheses.
It is possible that this experiment did not reproduce the mild T-tubule defects in Jph2_Low that were observed by in situ T-tubule imaging (Figure 5) because the CM dissociation procedure affects T-tubule organization in some CMs and thereby increases within-group variation (compare error bars between Figure 5 and Figure 6). However, based on both in situ T-tubule analysis and CAV3 analysis on isolated CMs, it is clear that JPH2 has a minor direct function in T-tubule maturation. Substantial T-tubule disruption was only observed when JPH2 was depleted in a large fraction of CMs, resulting in cardiac stress and associated secondary effects on CMs (Figure 6D).

We next evaluated whether the varied effect of JPH2 depletion on T-tubule organization influences Ca\textsuperscript{2+} handling. Freshly dissociated CMs were loaded with the Ca\textsuperscript{2+}-sensitive dye Rhod-2 AM, and Ca\textsuperscript{2+} transients were measured by confocal line scan imaging. Both transduced and nontransduced Jph2_High CMs exhibited significantly reduced Ca\textsuperscript{2+} transient amplitude, prolonged time to peak, and slower time to 50% decay (Figure 7A and 7B), which is consistent with previous studies of JPH2's role in Ca\textsuperscript{2+} handling. However, the major effect was likely secondary to heart failure and not directly attributable to JPH2 depletion because the difference with TNT-Cre control and Jph2_High CMs was greater than the difference between GFP\textsuperscript{+} and GFP\textsuperscript{−} CMs within Jph2_High. Ca\textsuperscript{2+} transient amplitude was more severely depressed in GFP\textsuperscript{+} than GFP\textsuperscript{−} Jph2_High CMs, consistent with

the more severe T-tubule abnormalities observed in GFP+ versus GFP− Jph2_High CMs. Jph2_Low GFP+ CMs had Ca2+ transients with mildly but significantly reduced peak amplitude compared with GFP− CMs isolated from the same heart. No significant change in time to peak or time to 50% decay was detected (Figure 7C and 7D). This is consistent with the minor effect of JPH2 depletion on T-tubule morphology in Jph2_Low. These single-cell measurements of Ca2+ handling paralleled our imaging data on T-tubule structure and indicate that JPH2 has a minor cell-autonomous role in establishing Ca2+ release unit function.

Figure 6. Transverse tubule (T-tubule) analysis in cardiac myocytes (CMs) that were isolated from hearts under serial levels of mosaic junctophilin-2 (JPH2) depletion. A, Representative images of CAV3 and JPH2 staining in CMs isolated from postnatal day (P21) hearts under control or different levels of mosaic JPH2 depletion. Scale bar, 50 μm. CAV3 patterns in white boxes were enlarged and skeletonized in (B). C, AutoTT quantification of T-tubule patterns in isolated CMs. Number of CMs analyzed was shown in columns in (C). CMs were dissociated from 3 hearts per group. Student t test: **P<0.01; ***P<0.001. Nonsignificant P values are shown in parentheses. Plots show mean±SD. D, JPH2 depletion had a small cell-autonomous effect of T-tubule structure. Depletion in a large fraction of cardiac myocytes caused heart failure, which indirectly disrupted T-tubule structure. TNT indicates troponin-T.

CASAAV-Based Screen Identifies RYR2 as a Novel T-Tubule Regulator
Mosaic mutagenesis by CASAAV avoids the time-consuming procedure of generating genetically modified mice. A large number of AAVs that deliver gRNAs directed at different genes can be generated side by side simultaneously. Thus, this technology allowed us to perform a genetic screen for novel T-tubule regulators. Using a candidate-based approach, we generated AAVs targeting 8 genes that could be potentially important for T-tubule maturation. These genes encode important cardiac transcriptional factors (NKX2-5.
[NK2 homeobox 5], TBX5 [T-box 5], MEF2C [myocyte enhancer factor 2C], and TEAD1 [TEA domain family member 1]) and T-tubule–associated proteins (RYR2, CACNA1C [calcium voltage-gated channel subunit alpha1 C], CAV3, and NCX1 [sodium-calcium exchanger 1]). We injected each of these viruses into P1 Rosa26 Cas9-P2A-GFP mice at a low dose (similar to that used in Jph2_Low), dissociated the hearts at P21, and performed JPH2 immunostaining to image T-tubule morphology in GFP+ CMs (Figure 8A). GFP− CMs from the same heart were used as internal negative controls.

![Diagram](image_url)

**Figure 7.** Effect of junctophilin-2 (JPH2) depletion on Ca2+ transients in ventricular cardiac myocytes (CMs). CMs were dissociated from control, Jph2_High (A and B), or Jph2_Low (C and D) treatment groups. CMs were loaded with the Ca2+-sensitive dye Rhod-2 AM (acetoxymethyl) and imaged by confocal line scan. Representative Ca2+ transient profiles recorded from cardiac myocytes paced at 1 Hz are shown in A and C, and quantitative data are shown in B and D, plotted as mean±SD. Number within bars indicates the number of CMs whose data were pooled to calculate the bar. These CMs were isolated from 3 hearts per group. Groups were compared by t test.

**P**<0.01. ***P**<0.001. Nonsignificant **P** values are shown in parentheses. TNT indicates troponin-T.
controls. Efficient depletion of NKX2-5, TEAD1, RYR2, and CAV3 was validated by immunostaining (Online Figure VI; Figure 8C and 8D).

Through this screen, we found that RYR2 depletion caused dramatic disruption of the JPH2 staining pattern (Figure 8A and 8B). By contrast, the AAVs targeting the other 7 genes did not show this effect. Efficient depletion of RYR2 was observed in ≈65% of the AAV-infected GFP+ CMs (Figure 8C and 8D). Mice with mosaic RYR2 depletion in a minority of CMs (only ≈10% of total CMs were depleted of RYR2) maintained normal heart function (Figure 8E). Dramatic T-tubule disruption was observed in GFP+ CMs under in situ T-tubule imaging, but GFP-neighboring cells retained normal T-tubule patterns (Figure 8F and 8G; see additional representative confocal z stacks in Online Movie IV). This phenotype was also confirmed in isolated CMs, as RYR2− CMs exhibited disrupted CAV3 staining pattern, whereas normal CAV3 pattern was observed in RYR2+ CMs (Figure 8H and 8I). The effect of RYR2 depletion on T-tubule structure staining pattern was reproduced with 2 additional independent pairs of gRNAs (Online Figure VII), which ruled out off-target effects. Together, these data show a novel cell-autonomous function of RYR2 in T-tubule maturation.
Discussion

In this study, we combined AAV-mediated mosaic transduction and CRISPR/Cas9-based somatic mutagenesis to establish a powerful technical platform, named CASAAV, which permits facile interrogation of cell-autonomous gene function in the postnatal heart. We also demonstrate the value of a genetic mosaic strategy to disentangle direct, cell-autonomous roles of a gene from changes that arise from effects on overall organ function. We anticipate that this strategy will allow the rapid and precise interrogation of gene function in the postnatal heart in diverse processes such as CM maturation, regeneration, and hypertrophy.

Somatic cardiac mutagenesis using a Cre-activated Myh6-Cas9 allele was described previously. Our study used the more widely available Rosa26<sup>Cre<sub> Cas9</sub></sup> mouse line, which retains CM-selective gene inactivation in the heart because of the cardiotoxic properties of AAV9 and cTNT-Cre-driven Cas9 activation. More importantly, our study focused on mosaic analysis of cell-autonomous phenotypes as a strength of the Cas9 somatic mutagenesis strategy. We performed foundational experiments that are required to fully exploit this strategy, including the demonstration that the dose of AAV mainly affects the frequency of transduced CMs but has only a small effect on the efficiency of gene inactivation among those CMs that are transduced. Furthermore, we provide data on the overall knockout efficiency of the system, demonstrate that tandem gRNAs targeting the same gene enhances knockout efficiency, and reveal the combination of mechanisms that collectively ensure a high knockout efficiency.

We combined CASAAV with in situ T-tubule imaging to study the genetic regulation of CM maturation in vivo. At a full virus dose to maximize the transduction of CMs, CASAAV fully recapitulated observations made using more traditional genetic models. For example, when JPH2 was depleted in a large fraction of CMs (Jph2<sub>High</sub> and Jph2<sub>Full</sub>), the heart exhibited ventricular dilatation, CM hypertrophy, and heart failure, which were all consistent with previous studies of Mhy6-Cre; Jph2-shRNA mice. Dramatic T-tubule defects and Ca<sup>2+</sup> transient abnormalities in Jph2<sub>High</sub> and Jph2<sub>Full</sub>, the heart exhibited ventricular dilatation, CM hypertrophy, and heart failure, which were all consistent with previous studies of Mhy6-Cre; Jph2-shRNA mice. Dramatic T-tubule defects and Ca<sup>2+</sup> transient abnormalities in Jph2<sub>High</sub> and Jph2<sub>Full</sub>, the heart exhibited ventricular dilatation, CM hypertrophy, and heart failure, which were all consistent with previous studies of Mhy6-Cre; Jph2-shRNA mice. Dramatic T-tubule defects and Ca<sup>2+</sup> transient abnormalities in Jph2<sub>High</sub> and Jph2<sub>Full</sub>, the heart exhibited ventricular dilatation, CM hypertrophy, and heart failure, which were all consistent with previous studies of Mhy6-Cre; Jph2-shRNA mice. Dramatic T-tubule defects and Ca<sup>2+</sup> transient abnormalities in Jph2<sub>High</sub> and Jph2<sub>Full</sub>, the heart exhibited ventricular dilatation, CM hypertrophy, and heart failure, which were all consistent with previous studies of Mhy6-Cre; Jph2-shRNA mice.

A particular strength of the CASAAV system is the ability to rapidly generate genetic mosaics, which permits precise delineation of gene function that is difficult to achieve using constitutive or even inducible knockout models. For example, because JPH2 depletion caused early-onset heart failure, which itself is associated with T-tubule disruption, studies in traditional JPH2 knockout mice were unable to disentangle the direct role of JPH2 on T-tubule maturation from its role to stabilize T-tubules in the face of cardiac dysfunction. By using a low dose of AAV to direct JPH2 depletion, we were able to separate the function of JPH2 in T-tubule maturation from its requirement to stabilize T-tubules in heart failure. In CMs from Jph2<sub>Low</sub> mice that lacked JPH2 but had overall preserved heart function, we observed very mild T-tubule defects. However, as we increased the fraction of CMs that lack JPH2, we observed worsening T-tubule defects in both transduced and nontransduced CMs that paralleled the extent of heart dysfunction. These observations are consistent with previous studies and suggest that widespread JPH2 depletion primarily affects T-tubule organization by impairing heart function. In failing hearts, we did observe that JPH2-depleted CMs had more severe T-tubule disruption than JPH2-replete CMs, supporting a role for JPH2 to stabilize T-tubules in the face of CM stress caused by heart dysfunction, as previously reported. However, contrary to previous studies of JPH2 depletion done in the context of heart dysfunction, our genetic mosaic approach shows that JPH2 has a minor cell-autonomous role in T-tubule maturation. This role of JPH2 was mirrored in its modest but measurable effects on Ca<sup>2+</sup> transient amplitude, which suggests that JPH2 may regulate RYR2 activation within Ca<sup>2+</sup> release units. A broader implication of these results is that studies of CM maturation or function need to use strategies such as genetic mosaicism to distinguish direct cell-autonomous gene function from effects of gene inactivation that occur secondary to organ function impairment.

Another advantage of performing mosaic mutagenesis is that it permits study of genes that are essential for animal survival. For example, because RYR2 is the core Ca<sup>2+</sup> channel that directly drives heart contraction, RYR2 knockout rapidly causes embryonic death, precluding its detailed functional analysis in vivo in the postnatal heart. By contrast, through AAV-based mosaic knockout, we were able to study the in vivo function of RYR2 in adult CMs while maintaining normal heart function. This provided us with the unprecedented opportunity to identify a novel role of RYR2 in T-tubule organization. Thus, the CASAAV platform opens the door to precisely investigate the cellular functions of essential genes in vivo, which otherwise would be technically inaccessible.

In vivo screen identified RYR2 as a previously undescribed regulator of T-tubule maturation. Further experiments will be required to define how RYR2 regulates T-tubule maturation. One possibility is that RYR2, located on junctional SR, serves a structural role by providing a scaffold that interacts with proteins on T-tubules. Another possibility is that normal Ca<sup>2+</sup> oscillations conducted through RYR2 are required to promote formation and maturation of T-tubules.

Because CRISPR/Cas9 provides the versatility to target most genes in the genome and CASAAV avoids the time and resources required to generate genetically modified mice, this technology greatly expedites the use of genetic loss-of-function strategies to study gene function in the postnatal heart. In our hands, the whole procedure from gene selection to phenotypic characterization of T-tubules in knockout CM can be done within 6 weeks. As a result, we were able to perform the in vivo screen that led to identification of RYR2 as a novel T-tubule regulator. Thus, this technology is well suited for in vivo genetic screening for regulators of CM phenotypes, such as maturation and hypertrophy.

Adenoviral and AAV-mediated delivery of short hairpin RNAs (shRNAs) have been previously used to knockdown genes in postnatal CMs. Compared with short hairpin RNAs,
CASAAV has clear advantages. ShRNAs are unable to achieve complete protein depletion, and >70% depletion is often considered successful knockdown. ShRNAs must actively bind to target transcripts, so that knockdown depends on continued shRNA expression at sufficient levels compared with the endogenous transcript. With CASAAV, a subset of cells with homozygous truncating mutations will have complete protein depletion. Furthermore, CASAAV irreversibly modifies the genome, which makes gene knockdown irreversible, more potent than shRNAs, and likely accounts for the relative insensitivity of gene depletion efficiency among transduced cells to overall viral dose, a critical feature for the mosaic strategy.

The CASAAV system has some limitations. First, we are unaware of efficient homology-directed repair in terminally differentiated cells, making targeted knockin mutations infeasible. Second, as with RNA interference-based knockdown strategies, one should be cognizant of potential off-target activity and control for this possibility by careful gRNA design and, optimally, use of ≥2 independent gRNA pairs to target the same gene. Third, the possibility of gain-of-function mutations should be considered, for example, if the gRNA leads to C-terminal truncation and a dominant negative N-terminal protein fragment. We used gRNAs targeting near the N terminus of genes to minimize this possibility. Fourth, for the mosaic strategy to be successful, one needs means to identify individual cells that have undergone gene inactivation. Immunostaining with a high-quality antibody is one such assay. Alternatively, if the fraction of cells that have undergone gene depletion is sufficiently high, one can use GFP from Rosa26Cas9-GFP as a surrogate marker. When doing so, one should also be aware that a low fraction of GFP-negative cells also could have undergone Cas9 mutagenesis but have lost GFP expression. Typically, this can be overcome by studying a large number of single cells.

In summary, we have developed a rapid and powerful technical platform for gene inactivation in postnatal CMs. This platform is particularly well suited for genetic mosaic analysis of genes to define the cell-autonomous functions. In the future, we anticipate that the capabilities of this system will be further extended by pairing it with single-cell functional phenotyping and single-cell RNA-seq.

A. Detailed Materials and Methods

Plasmid construction

AAV-U6-TnT-Cre ITR plasmid was developed by modification of PX552 (Addgene #60958). PX552 was digested with XbaI and HindIII to remove the hSyn promoter and eGFP cDNA. A 414 bp chicken cardiac Troponin T promoter + β Globin intron and Cre cDNA was PCR amplified with primers tagged with Spel 5’ and HindIII 3’ from an AAV-TnT-Cre plasmid reported previously. The TnT-Cre amplicon was then cloned into the digested PX552 vector. Addition of a second U6 promoter and gRNA scaffold was achieved by cloning the second U6 promoter and a 5’ AarI site into the MluI site upstream of the first U6 promoter. An additional AarI site and the second gRNA scaffold was then cloned into the same MluI site. See Online Fig. I for the map of gRNA cloning strategy this plasmid. gRNAs (Online Table I) were designed using an online tool (http://crispr.mit.edu/) and cloned into the first or second U6 promoter cloning sites.

AAV9 production

AAV9 was prepared using standard protocols with modifications. In brief, AAV-ITR plasmids, AAV9-Rep-Cap, and pHelper (pAd-deltaF6, Penn Vector Core) plasmids were produced by maxiprep (Invitrogen, K210017). Triple transfection into AAV293 cells (Agilent, 240073) was performed using PEI transfection reagent (Polysciences, 23966-2). 60h after transfection, cells were scraped off of plates, resuspended in lysis buffer (20 mM Tris pH 8, 150 mM NaCl, 1 mM MgCl2, 50 µg/ml Benzonase) and lysed by three freeze-thaw cycles. AAV9 was precipitated by PEG8000 (VWR, 97061-100) and re-suspended in lysis buffer. AAV was purified in a density gradient (Cosmo Bio USA, AXS-1114542) by ultracentrifugation (Beckman, XL-90) with a VTi-50 rotor and concentrated in PBS using a 100 kDa filter tube (Fisher Scientific, UFC910024). AAV titer was quantified by Q-PCR (primer sequences in Online Table II) using a fragment of the TNT promoter DNA to make a standard curve.

Animal experiments

All animal procedures were approved by the Institutional Animal Care and Use Committee of Boston Children’s Hospital. RosaCas9GFP/Cas9GFP and Rosa tdTomato/tdTomato mice were acquired from the Jackson Laboratory.

To inject AAV into P1 pups, the body weight of the animals was measured and the pups were anesthetized in an isoflurane chamber. The amount of AAV was calculated according to body weight and injected subcutaneously.

Echocardiography was performed on a VisualSonics Vevo 2100 with Vevostrain software. Animals were awake during this procedure and held in a standard handgrip. Echocardiography was performed blinded to treatment group.
Gene expression analysis

Total RNA was purified from the heart apex using PureLink RNA Mini kit (Ambion, 12183025). Genomic DNA removal from RNA and reverse transcription was performed using QuantiTech reverse transcription kit (Qiagen, 205311). Real-time PCR was performed using an ABI 7500 thermocycler with Power SYBR Green PCR kit (ThermoFisher, 4368702). Primers are listed in Online Table II.

Amplicon Sequencing

Primers that were used to generate DNA libraries are listed in Online Table II. DNA library construction protocol was modified from our previous protocol\(^3\). In brief, targeted cDNA sequences were amplified by PCR using Phusion High-Fidelity DNA polymerase (NEB, M0530S). The amplicons were next phosphorylated by T4 polynucleotide kinase (NEB, M0201S) and adenylated by Klenow fragment (3'-5' exo-) (NEB, M0212S). Adaptor primers were phosphorylated, annealed and ligated to both ends of the amplicons through T-A ligation using Quick Ligation kit (NEB, M2200S). Multiplexing primers were next used to barcode and PCR amplify the DNA libraries. After each step above, DNA was purified by AMPure XP beads (Beckman, A63881) under 1.6X conditions. Then an equal amount of each library was pooled together and gel purified to remove free primers and primer dimers. 250 bp paired end sequencing was performed on a MiSeq Sequencer (Illumina).

Amplicon-Seq reads were first quality controlled and trimmed to remove adapter sequences (Multiplexing adapter 1: p-GATCGGAAGAGCACACGTCT, Multiplexing adapter 2: ACACTCTTTCCCTACACGACGCTCTTCCGATCT) using Trim Galore (a wrapper tool around Cutadapt\(^4\) and FastQC (http://www.bioinformatics.babraham.ac.uk/projects/trim_galore/). Insertions/deletions in the trimmed sequencing libraries were then quantified using CRISPRezzo software\(^5\) run with the optional parameters -g, -c and --hide_mutations_outside_window_NHEJ. For analyzing amplicon 1&2, we ran CRISPRezzo in single-end mode (using read1 files) as the read length was longer than the amplicon size. However amplicon 3 is 512 bp in size and therefore we analyzed it by utilizing the paired end option (using parameter -r2 to specify read2 files).

Cardiomyocyte isolation and culture

Cardiomyocytes were isolated by Langendorff perfusion using an established protocol\(^6\) with modifications. In brief, heparin-injected mice were anesthetized in an isoflurane chamber. Hearts were isolated and cannulated onto the perfusion apparatus. Perfusion buffer [10 mM Hepes (pH 7.4), 120.4 mM NaCl, 14.7 mM KCl, 0.6 mM KH\(_2\)PO\(_4\), 0.6 mM Na\(_2\)HPO\(_4\), 1.2 mM MgSO\(_4\), 4.6 mM NaHCO\(_3\), 30 mM Taurine, 10 mM 2,3-butanedione monoxime, 5.5 mM glucose] was pumped into the heart to clear blood and equilibrate the organ. Retrograde perfusion of collagenase II (Worthington, LS004177) was performed in the heart for 10 min at 37 °C to dissociate
cardiomyocytes. Heart apex was cut from the digested heart, manually dissociated into single cardiomyocytes in 10% FBS/perfusion buffer, and filtered through a 100 µm cell strainer to remove undigested tissues. The isolated cardiomyocytes were concentrated by 20 x g low-speed centrifugation for 4 min and re-suspended in short-term culture medium (DMEM (Gibco), 10% FBS, pen/strep (Gibco), 10 µM Blebbistatin). Cardiomyocytes were cultured on laminin-coated coverslips in culture medium for <1 h at 37 °C with 5% CO₂ before fixation.

Flow Cytometry
For flow cytometry analysis, freshly isolated CMs were passed through a 100 µm cell strainer and centrifuged at 20 x g for 5 minutes at room temperature. Non-myocytes in the supernatant were discarded and the pelleted CMs were resuspended in 2.5 ml of PBS. Fluorescence data were collected on a Propel Laboratories Avalon cytometer with a 100 µm nozzle and standard GFP/RFP filter sets. Data were further analyzed using BioRad ProSort software.

For FACS, CMs from each heart were passed through a 100 µm cell strainer, centrifuge at 20 x g for 5min at RT, resuspended in ~1ml perfusion buffer. FACS were performed using a BD AriaII SORP cell sorter with a 100 µm nozzle. GFP+ CMs were collected in 1.5 ml Eppendorff tubes with cold perfusion buffer.

Histology analysis
After mice were euthanized by CO₂, body weight was measured using a digital benchtop scale (Sartorius, AY123). Hearts were removed, gently blotted to remove liquid, and weighed using an analytical balance (Fisher Science Education). Bright-field images of whole hearts were taken under a dissection microscope (Zeiss, SteREO Discovery V8). Images of hearts that were isolated from mice with similar body weights (<10% difference) were put together for comparison.

Hearts were fixed by 4% paraformaldehyde overnight at 4 °C and cryoprotected by washing in 15% followed by 30% sucrose. Hearts were embedded in tissue freezing medium (General Data, TFM-5). 10 µm cryo-sections were cut using a cryostat (Thermo Scientific, Microm HM 550).

Hematoxylin & eosin staining was performed on cryo-sections. Sections were first air dried at room temperature, stained with 0.1% Mayers Hematoxylin for 10 min and rinsed in water for 5 min. Next the sections were dipped in 0.5% Eosin for 2 min and rinsed in water for 2 min. Then the sections were dipped in 50%, 70%, 95%, 100% ethanol and Xylene. After air drying, the sections were mounted using VectaMount permanent mounting medium (Vector Laboratories, H5000).

Immunofluorescence
Isolated cardiomyocytes were immunostained as described previously⁷,⁸. In brief, cardiomyocytes in culture were fixed on coverslips by 4% paraformaldehyde/PBS for 10
min, permeabilized by 0.1% Triton-100/PBS for 10 min, and blocked in 4% BSA/PBS at room temperature for 1 h. Then the cells were incubated with primary antibodies diluted in blocking buffer overnight at 4 °C. After three 5 min washes with blocking buffer, the cells were incubated with secondary antibodies and dyes at room temperature for 2 h. Then the cells were washed with PBS three times and mounted with ProLong Diamond antifade mountant (Invitrogen, 36961)

To immunostain tissue sections, frozen sections were first warmed to room temperature, incubated with 0.1% Triton-100/PBS for 10 min, and blocked with 4% normal donkey serum/PBS at room temperature for 2 h. Then the cells were incubated with primary antibodies diluted in blocking buffer overnight at 4 degree. After three 15 min washes with blocking buffer, the cells were incubated with secondary antibodies with/without WGA and/or DAPI at room temperature for 2 h. Then the sections were washed with PBS for 15 min/each for three times and mounted with ProLong Diamond antifade mountant (Invitrogen, 36961)

All antibodies and dyes used in this study are listed in Online Table III.

Western blot

FACS sorted CMs were lysed in 2X SDS sample buffer at 2000 cell/ul concentration to normalize protein contents. After boiled for 5 min, 5 µl cell lysate of each sample was separated on a 4%-12% gradient gel (Invitrogen, Bolt gels, NW04122BOX), transferred to a PDVF membrane, and blocked by 4% milk/TBST. Primary antibodies were incubated with the membrane overnight at 4°C, followed by four 15min TBST washes. HRP-conjugated secondary antibodies were probed for 1~2h at RT, followed by four 15 min TBST washes. After adding Immobilon Western chemiluminescent HRP substrate (Millipore, WBKLS0500), chemiluminescence were detected by a Li-Cor C-DigIt blot scanner.

All antibodies used in this study are listed in Online Table III.

In situ confocal T-tubule imaging

In situ T-tubule imaging was performed following a published protocol with modifications. In brief, hearts were dissected from euthanized animals and cannulated on a Langendorff apparatus. 100 µg/ml FM 4-64 (Invitrogen, 13320) was loaded into the heart by retrograde perfusion at room temperature for 10 min. The heart was next removed from the perfusion system, positioned on a glass-bottom dish, and immediately imaged by confocal microscopy.

Microscopy and image analysis

All bright-field images was taken under a stereomicroscope (Zeiss SteREO Discovery V8) with an AxioCam MRc camera. All confocal fluorescence images were taken using Olympus FV1000 inverted laser scanning confocal microscope equipped with an EM-CCD camera. A 60X/1.3 silicone-oil objective was used to image all
intracellular structures including t-tubule, sarcomere and nuclei. A 10X air objective was used to image whole tissue sections. Brightness and contrast were adjusted using ImageJ. All cell-counting-based quantification was performed manually under Nikon Eclipse 90i microscope with a Plan Fluor 40x/0.75 objective.

For JPH2 immunofluorescence intensity measurement on single cells, all cells were cultured, stained and imaged side-by-side under the same conditions on the same day. Cell boundary was manually drawn on maximally projected images and the average pixel intensity within the outlined images was measured using ImageJ. Background intensity was determined by measuring cell-free areas and was subtracted from the JPH2 average intensity.

Quantification of T-tubule and sarcomere were performed using AutoTT v1.0 software\textsuperscript{10}.

**Intracellular Ca\textsuperscript{2+} imaging**

Intracellular Ca\textsuperscript{2+} recordings were performed after loading CMs with Rhod-2 AM (8 µmol/L, Molecular Probes) for 30 min. After loading, CMs were subsequently washed with normal Tyrode solution (NaCl, 140 mM; KCl, 4 mM; MgCl\textsubscript{2}, 1 mM; CaCl\textsubscript{2}, 1.8 mM; Glucose, 10 mM; and HEPES, 5 mM, pH = 7.4, adjusted with NaOH) to remove the excess dye for 20 min. Cells were electrically stimulated at 1 Hz to produce steady-state conditions. All image data were acquired in the line scanning mode along the long axis of the cell. Line scan was positioned in the cytosol, avoiding the nuclear area. Ca\textsuperscript{2+} levels were reported as \(F/F_0\), where \(F_0\) is the resting Ca\textsuperscript{2+} fluorescence. A Olympus FV1000 inverted laser scanning confocal microscope with a 60X/1.3 silicone-oil objective was used for confocal fluorescence imaging by line scan.

E. Online Movies

Online Movie I. *In situ* T-tubule imaging in a Jph2_Low heart.
Online Movie II. *In situ* T-tubule imaging in a Jph2_Mid heart.
Online Movie III. *In situ* T-tubule imaging in a Jph2_High heart.
Online Movie IV. *In situ* T-tubule imaging in a RYR2 mosaic mutagenesis heart.

All movies are confocal z-stacks with 2 µm step size that play at 1 stack/second speed. Each movie contains an FM4-64 grey-scale channel to the left and an RGB channel to the right that merges FM4-64 (Magenta) and Cas9GFP (Green) signals. The height of all movie frames is 212 µm.
Online Figure I. AAV ITR vector for delivery of tandem guide RNAs and cTNT Cre. The targeting sequences for gRNA1 and gRNA2 are inserted after AarI or SapI restriction digestion, respectively.
Online Figure II. Distribution of GFP and tdTomato reporters in Rosa26Cas9GFP/tdTomato mice after treatment with AAV9:TNT-Cre. Neonatal mice were treated with AAV:TNT-Cre. Cardiomyocytes were dissociated from adult hearts and analyzed by flow cytometry. As expected, most cardiomyocytes were GFP+ tdTomato+ and there were few GFP+ tdTomato– cells. However, GFP– tdTomato+ cells were noted. This might reflect differential sensitivity of the two different Cre-activated reporters to Cre, and differential sensitivity of GFP or tdTomato expression or stability in cardiomyocytes stressed by dissociation and flow cytometry.
Online Figure III. Frame-shift mutations induced by Jph2gRNA-directed Cas9 cleavage followed by NHEJ. (A) The number of predicted off-target sites in the mouse genome for gRNA1 or gRNA2. (B-C) Examples of mutations induced by Jph2gRNA1 or Jph2gRNA2 as determined by amplicon sequencing.
Online Figure IV. JPH2 immunoblot of FACS-sorted GFP+ CMs treated with TNT-Cre or Jph2(gRNA1+2) AAV. This is the full immunoblot of the same gel shown in Fig. 1G, over-exposed to look for minor truncated Jph2 expression products. The major effect of Jph2 gRNAs was reduction of JPH2 level rather than production of a truncated protein.
Online Figure V. JPH2 depletion did not cell-autonomously disrupt sarcomere organization. TNT-Cre or AAV-gRNA(Jph2) were administered at P1 and CMs were isolated at P21. CMs were immunostained for JPH2 and ACTN2. (A). Representative maximal intensity projection images. (B) Longitudinal distribution of ACTN2 fluorescence intensity in a single focal plane of boxed areas in (A). AU, arbitrary unit. (C-D) Quantification of average distance between Z-lines and the regulatiry of Z-line alignment by AutoTT. Boxed areas in (A) were representative regions that were used to perform this quantification. n=30 CMs isolated from 3 hearts in each group. Student’s t-test compared to control (TNT-Cre) cells. ns, not significant. Plots show mean ± SD.
Online Figure VI. Knockout of NKX2-5, TEAD1 and CAV3 by CASAAV. (A) Immunofluorescence images showing depletion of NKX2-5 (top), TEAD1 (middle) and CAV3 (bottom) in Cas9GFP+ CMs upon mosaic transduction with AAVs that express corresponding gRNAs. Arrows point to nuclear depletion of NKX2-5 and TEAD1. CAV3-depleted cell is delineated by dashed lines. Scale bar, 20 µm. (B) Quantification of NKX2-5, TEAD1 and CAV3 depletion in GFP- and GFP+ CMs. n=3 hearts. >50 CMs were counted per heart. Student’s t-test: ***p<0.001. Plots show mean ± SD.
Online Figure VII. Mosaic RYR2 depletion using multiple gRNA pairs disrupts T-tubule structure. (A) RYR2 was depleted using two different pairs of gRNAs. RYR2 and CAV3 were detected by immunostaining, and GFP was detected by endogenous fluorescence. Representative images show that CAV3 T-tubule staining was disrupted by depletion of RYR2 in Cas9GFP+ CMs. Scale bar, 10 micron. (B) Quantification of CAV3 immunostaining using AutoTT, displayed as violin plots. CMs depleted of RYR2 by either pair of gRNAs had reduced T-tubule organization. Student’s t-test: *** P<0.001.
